Diminished motivation is associated with robust impairment in psychosocial functioning in schizophrenia (SZ). Little is known about the reciprocal relationships between motivation and functioning, particularly following a first episode of psychosis. We tested bidirectional associations between motivation and social and occupational functioning in the year following a first episode of SZ spectrum disorder among patients in the Recovery After an Initial Schizophrenia Episode—Early Treatment Program (RAISE-ETP) study. Four hundred four individuals (aged 15–40) who presented with a first episode of SZ spectrum disorder (eg, SZ, schizoaffective or schizophreniform disorder, psychotic disorder not otherwise specified) completed assessments of work and school functioning, social functioning, and motivation at 6- and 12-month follow-up, controlling for assessments at study entry. Controlling for cognition, and psychotic and depressive symptoms measured at each time point, motivation at 6 months was associated with work and school participation at 12 months, but work and school participation at 6 months was not associated with motivation at 12 months. Conversely, social functioning at 6 months was associated with motivation at 12 months, but motivation at 6 months was not associated with social functioning at 12 months. Findings suggest that motivation is associated with later occupational, but not social, functioning in the first year following an initial episode of psychosis. Social functioning, on the other hand, is associated with later motivation. Future intervention trials focused on improving occupational functioning in this population may benefit from targeting patient motivation directly (eg, through motivational interviewing), or indirectly by improving relationships and support networks.

Key words: motivation/psychosocial functioning/first episode psychosis/schizophrenia/cross-lagged analysis

Introduction

Impairments in motivation and psychosocial functioning (ie, occupational and social functioning) are cardinal features of schizophrenia (SZ) spectrum disorders. These impairments precede the onset of disorder,^{1,2} persist over the long-term course,^{3,4} and present a challenge to treatment.^{5,6} Motivation is a complex construct that has received renewed interest in the context of negative symptoms in SZ.^{7,8} Negative symptoms have been empirically divided into *expressive* and *experiential* domains.^{7,9} Expressive symptoms consist of affective flattening and alogia, while experiential symptoms are characterized by anhedonia, reduced social drive, and amotivation.⁷ Amotivation, in particular, shows robust association with psychosocial functioning impairments in SZ.^{10,11} In general models of motivation, deficits in “liking” (ie, in-the-moment pleasure) appear to be more associated with anhedonia, or diminished interest/pleasure, while deficits in “wanting” (ie, anticipation of pleasure and associated drive) tend to be more associated with deficits in motivated behavior.^{12,13} Deficits in “wanting,” which are associated with mesolimbic dopaminergic transmission in animal models, have been identified as key contributors to amotivation and associated impairments in goal-directed behavior in SZ.¹⁴

When motivation and functioning are measured concurrently, as much as 50%–75% of the variance is shared between them.^{15–17} Much of this shared variance may be due to item overlap in the measures typically used to assess amotivation within the context of negative symptoms broadly defined. The Scale for the Assessment of Negative Symptoms (SANS¹⁸), for example, includes

questions covering impersistence at work or school as a key indicator of avolition/apathy. Those not participating in work or school will receive a higher score on this scale, conflating the two constructs. Only more recently has there been a movement in the field to develop negative symptom measures that more specifically assess experiential symptoms, including amotivation.^{19,20} Thus, most of what we currently know about the connection between motivation and functioning is derived from studies using less sensitive assessments of negative symptoms. In addition, reduced functioning is undoubtedly driven by a multitude of factors in SZ, such as cognitive impairment^{21,22} and positive,^{23,24} negative,^{2,25} and depressive^{2,26} symptoms. The disruptive effects of psychotic episodes and hospitalizations could also impair functioning through demoralization and, relatedly, reduced motivation.²⁷

While standard measures of negative symptoms often fail to capture amotivation specifically, items from the Quality of Life Scale (QLS²⁸)—motivation, sense of purpose, and curiosity—have shown consistent associations with goal-directed behavior and psychosocial functioning in SZ.^{25,27} These items also demonstrate convergent validity in their association with avolition as measured by the Schedule for the Deficit Syndrome (SDS²⁹),³⁰ an instrument originally developed to identify patients with primary negative symptom-based deficits, including a reduced sense of purpose and social drive.

Given the lack of examination of the reciprocal associations over time in studies of first episode SZ, it is difficult to infer the relative primacy of these constructs. In addition, the tendency to combine occupational and social functioning into a single outcome precludes evaluation of the potential for differential associations with motivation.

To address these questions, in the current study we examined the prospective, reciprocal associations between motivation and social and occupational functioning in a large sample of patients following a first episode of SZ. Because social and occupational functioning are only moderately correlated in SZ,^{31,32} we examined these variables separately. We conducted cross-lagged panel analysis using structural equation modeling to examine (a) whether motivation following an initial episode of SZ was associated with subsequent occupational and social functioning, (b) whether psychosocial functioning was associated with later levels of motivation, or (c) both. Because longitudinal evidence suggests motivation can influence functioning and vice versa, we explored the extent to which the two domains of functioning showed reciprocal associations with motivation over time.

Methods

Participants

Participants were part of the longitudinal multisite National Institute of Mental Health's (NIMH) Recovery

After an Initial Schizophrenia Episode—Early Treatment Program (RAISE-ETP).³³ RAISE-ETP was a cluster-randomized clinical trial that compared a comprehensive intervention for first episode SZ to usual community care. Four hundred four participants between the ages of 15 and 40 were recruited across 34 community mental health treatment centers in 21 states and were followed up for a minimum of 2 years. All participants received intervention lasting up to 2 years. Individuals were eligible if they had one of the following DSM-IV diagnoses: SZ, schizoaffective disorder, schizophreniform disorder, brief psychotic disorder, or psychotic disorder not otherwise specified. Individuals with clinically significant head trauma or other serious medical conditions were excluded. All participants had experienced only a single episode of psychosis and had ≤6 months of lifetime antipsychotic medication treatment. All participants provided written informed consent (as well as assent and parental/guardian consent for those under 18 years old). A more detailed description of recruitment procedures, clinical site selection and randomization, treatment components and outcomes is provided elsewhere.^{33–35}

Measures

Descriptive statistics of the sample and variables of interest are provided in [table 1](#). Diagnostic and assessment interviews were conducted using 2-way video conferencing completed by remote, centralized personnel (ie, individuals with training to provide research quality interviews who were blind to study design and assignment). One interviewer conducted all the assessments for a given participant at a given time point, but each participant could be assessed by different raters at different time points across the study. The following assessments relevant to the current report were conducted by the raters: the Structured Clinical Interview for DSM-IV (SCID)³⁶ to determine psychiatric diagnoses; the Positive and Negative Syndrome Scale (PANSS)³⁷ to assess psychotic symptoms; the Calgary Depression Scale for Schizophrenia (CDSS)³⁸ to assess symptoms of depression; and the Quality of Life Scale (QLS).³⁷ The QLS is a 21-item scale that assesses qualities such as motivation, social interaction, and engagement in life roles and activities over the past month. Each QLS item is rated on a scale ranging from 0 to 6 with lower scores indicating more severe impairment. The scale is subdivided into the following 4 subscales: Intrapsychic Foundations, Interpersonal Relations, Instrumental Role Functioning, and Common Objects and Activities. The QLS, PANSS, and CDSS were completed every 6 months. Site-based personnel completed the following assessments: Brief Assessment of Cognition in Schizophrenia (BACS),³⁹ that includes tests of verbal memory, digit sequencing, token motor, verbal fluency, symbol coding, and tower of London; the Services Utilization Recording Form (SURF),⁴⁰ a questionnaire that documents health

Table 1. Study Sample Characteristics and Variable Descriptive Statistics

	Mean (SD) or %
Demographics	
Age	23.14 (5.07)
Gender: male	72.5%
Race	
American Indian or Alaskan Native	5.2%
Asian	3.0%
Black or African American	37.6%
Native Hawaiian or Other Pacific Islander	0.2%
White	54.0%
Ethnicity: Hispanic or Latino	18.1%
Outcome variables^a	
SURF work or school baseline	39.8%
SURF work or school 6 mo	71.8%
SURF work or school 12 mo	66.6%
QLS motivation baseline	7.61 (3.52)
QLS motivation 6 mo	8.52 (3.64)
QLS motivation 12 mo	8.31 (3.69)
QLS interpersonal relationships baseline	19.76 (8.70)
QLS interpersonal relationships 6 mo	22.88 (9.76)
QLS interpersonal relationships 12 mo	23.65 (9.51)
PANSS positive symptoms baseline	12.24 (3.83)
PANSS positive symptoms 6 mo	10.04 (4.18)
PANSS positive symptoms 12 mo	10.04 (3.74)
CDSS baseline	4.65 (4.28)
CDSS 6 mo	3.70 (4.33)
CDSS 12 mo	2.61 (3.52)
BACS baseline/12 mo	37.38 (7.02)

Note: BACS, Brief Assessment of Cognition in Schizophrenia; CDSS, Calgary Depression Scale for Schizophrenia; PANSS, Positive and Negative Syndrome Scale; QLS, Quality of Life Scale; SURF, Service Utilization Recording Form; mo, months. ^aNs range from 257 (12 mo) to 404 (baseline).

care services and indices of community participation (eg, work or school) present in the past month. The BACS was completed at baseline, 1-year and 2-year assessments, and the SURF was completed monthly.

Motivation. Our measure of motivation was based on 3 items of the Intrapsychic Foundations subscale of the QLS, including degree of motivation, sense of purpose, and curiosity. Example questions include “Have you had much enthusiasm, energy and drive?”, “Have you set any goals for yourself?”, and “How often have you seen or heard about something that you wanted to know more about or understand better?” These items have been used as an index of general motivation in various studies of people with SZ.^{17,27,41} In a recent factor analysis of the QLS, these 3 items loaded most strongly on the subscale.⁴²

Social Functioning. Social functioning was derived from the Interpersonal Relations subscale of the QLS. We used 7 items from the full scale: intimate interactions, active acquaintances, social activity, involved social network,

social initiatives, social withdrawal, and socio-sexual relationships. These items capture the multifaceted nature of social relationships, including the quantity (eg, “How many friends do you have”) and quality (eg, “Do you have friends with whom you are especially close other than your immediate family or the people you live with?”) of these relationships.

Occupational Functioning. Three items from the SURF (ie, Are you currently a student? Have you worked for pay during the past 30 days? Have you done any casual work or day jobs, such as yard work or babysitting for which you got paid?) were combined into a single score to measure work or school functioning at each assessment point (ie, the past month) and aggregated across 6-month time points; each was rated as either 0 = no (ie, no paid work and not a student) or 1 = yes (ie, paid work or a student). The goal of the current study was to examine the extent to which motivation at one point in time predicted involvement in work or school at a later time point (and vice versa), as these are the roles of greatest concern in young people who have recently developed SZ. Therefore, the SURF composite score was used to measure work or school involvement, rather than the more generic Instrumental Role Functioning subscale of the QLS, which focuses on functioning in the “home-maker” role for participants who are not “attempting” the role of student or worker.

Covariates. Psychotic symptom ratings were based on a Positive Symptom Factor Score of the following PANSS items: delusions, hallucinations, grandiosity, and unusual thought content.⁴³ Depression was calculated based on a total score on the CDSS. A composite score of cognitive functioning was created by computing the average of the six BACS tests; baseline and 12-month BACS scores were averaged in the current study to provide a stable indicator of cognitive ability; this was done because there was some evidence that cognitive functioning varied within participants from baseline to 12-month follow-up. We used subscale averages, as opposed to normed scores, as we were primarily interested in variance in motivation and psychosocial functioning accounted for by cognitive ability.

Although our focus in the current report is on motivation and social functioning, the QLS was originally designed to assess the multifaceted nature of intra- and interpersonal features of SZ. As such, although the PANSS also assesses negative symptoms, we did not include these items in the current analysis given their overlap with the QLS (correlations in the current sample range from .62 to .73) and the inclusion of symptoms in the PANSS that are less robustly related to functioning (eg, blunted affect).¹¹ (Because of the possibility of associations between expressive negative symptoms and psychosocial functioning, we tested the bivariate associations between blunted affect on the PANSS and our measures of psychosocial functioning (SURF work/school and QLS interpersonal relations). Associations

between blunted affect and work/school participation were small and nonsignificant at all time points (-0.05 to -0.10). Correlations between blunted affect and social functioning, however, ranged from -0.19 to -0.30 . While these are modest associations, we included blunted affect as a covariate at baseline, 6, and 12 months in the primary model testing the association of motivation and social functioning. The inclusion of blunted affect did not change the primary findings.)

Statistical Analyses

Before testing multivariate models, we examined the bivariate correlations among variables of interest across the 3 primary time points (baseline, 6-months, 12-months). We used structural equation modeling (SEM) to evaluate our primary research question, examining occupational and social functioning in separate models. We employed cross-lagged panel analysis to identify the degree to which motivation predicted functioning, and/or functioning predicted motivation, while controlling for previous and concurrent measurements of each variable (and other covariates). Models were tested in sequence, beginning with the autoregressive model (eg, motivation at 6 months predicting motivation at 12 months), then testing each directional model (eg, motivation at 6 months predicting occupational functioning at 12 months). We allowed residuals of the same variables measured across time to covary so as to minimize the impact of multicollinearity. In the case in which both directional associations were significant, fully cross-lagged models were tested, including the autoregressive and directional models simultaneously. Given the known associations among cognition, psychotic symptoms, and depression with motivation and psychosocial functioning, we included these variables as covariates in initial models. Ratings of symptoms of psychosis and depression at study entry (baseline), 6 months, and 12 months, and tests of cognition aggregated across baseline and 12 months, were included as covariates in these models. Path coefficients with P values $>.15$ were set to 0 in subsequent models.

These data were from a treatment trial of first-episode psychosis in which participants entering the trial had recently experienced an initial psychotic episode. Seventy-eight percent of participants had been hospitalized before study entry (median number of weeks since last hospitalization = 8). In addition, the primary outcomes of RAISE-ETP suggested that the most significant improvements in psychosocial functioning occurred by the 6-month time point.³⁴ Thus, to minimize the influence of symptom variance on the relationships between the variables of interest, we set the 6-month time point as the baseline, using the true baseline time point (ie, Month 0) for motivation and psychosocial functioning as control variables in all models. The treatment group was included as a moderating variable to examine the

impact of intervention on the variables of interest. We also accounted for clustering of observations by site. To examine the stability of associations over a longer period of time, we conducted sensitivity analyses aggregating the 12- and 18-month time points of the outcomes of interest among our primary models.

Model fit was assessed using standard criteria, including the χ^2 test, root mean square error of approximation (RMSEA), comparative fit index (CFI), and Tucker–Lewis index (TLI). For models with categorical outcomes, we compared fit using robust weighted least squares estimation. For models using continuous outcomes, we utilized χ^2 difference tests. Standardized coefficients are presented, and 2-tailed P values $<.05$ were considered statistically significant. Analyses were performed using Mplus version 7.4.

Results

Missing data due to treatment study dropout ranged from 0% (SURF) to 28% (QLS) at 6 months, and 21% (SURF) to 36% (QLS) at 12 months. Those who did not have follow-up data did not differ in the primary measures of interest at baseline from those who had follow-up data. Missing data were handled in the models using full information maximum likelihood. Bivariate correlations revealed significant associations among our primary variables of interest (supplementary table 1). Cognition (BACS) was unrelated to psychotic (PANSS positive symptoms) and depressive (CDSS) symptoms at all time points.

In preliminary SEM analyses, treatment group, duration of untreated psychosis, gender, age, or ethnicity did not moderate the associations between motivation and psychosocial functioning, so we did not include these variables in the models presented below. As predicted, cognition at baseline, and psychotic and depressive symptoms at corresponding time points were significantly associated with motivation and social and occupational functioning and were thus included as covariates in the models. See supplementary tables for BACS, PANSS, and CDSS coefficients.

Motivation and Occupational Functioning

We first tested the autoregressive model, examining the stability of motivation and occupational functioning across baseline, 6, and 12 months. The model provided adequate fit to the data ($\chi^2(43) = 54.734$, $P = .108$; RMSEA = 0.026; CFI = 0.994; TLI = 0.989). Next, we tested the model including motivation at 6 months as predictor of occupational functioning at 12 months, controlling for baseline assessments. Adding this path resulted in improved model fit ($\chi^2(41) = 49.979$, $P = .159$; RMSEA = 0.023; CFI = 0.995; TLI = 0.991), though the degree of improvement was at a trend level of significance

($\chi^2(2) = 5.328, P = .069$). Motivation at 6 months was significantly associated with occupational functioning at 12 months ($\beta = 0.190, SE = 0.062, P = .002$). We then tested the directional model in which occupational functioning at 6 months was associated with motivation at 12 months. Freeing this parameter resulted in adequate model fit ($\chi^2(41) = 53.928, P = .085; RMSEA = 0.028; CFI = 0.993; TLI = 0.988$), but did not improve fit from the baseline model ($\chi^2(2) = 0.133, P = .936$). Importantly, occupational functioning at 6 months was not associated with motivation at 12 months ($\beta = 0.036, SE = 0.066, P = .578$). Because this directional path was not significant, and model fit was not improved, we did not test the fully cross-lagged model with motivation and occupational functioning reciprocally linked. We therefore concluded that motivation at 6 months more likely influenced occupational functioning at 12 months than the reverse (figure 1).

Motivation and Social Functioning

The autoregressive model provided adequate fit to the data ($\chi^2(41) = 60.000, P = .028; RMSEA = 0.034; CFI = 0.980; TLI = 0.966$). The model including motivation at 6 months as a correlate of social functioning at 12 months, controlling for baseline assessments, resulted in adequate fit ($\chi^2(39) = 59.404, P = .019; RMSEA = 0.036; CFI = 0.978; TLI = 0.962$); however, motivation at 6 months was not associated with social functioning at 12 months ($\beta = 0.001, SE = 0.020, P = .994$). The directional model in which social functioning at 6 months was associated with motivation at 12 months resulted in adequate model fit ($\chi^2(39) = 50.823, P = .097; RMSEA = 0.027; CFI = 0.987; TLI = 0.978$), and there was a significant improvement in fit from the baseline model ($\chi^2(2) = 8.508, P < .001$). Importantly, social functioning at 6 months was associated with motivation at 12 months ($\beta = 0.497, SE = 0.195, P = .011$). Because only this directional path was significant, we did not test the fully cross-lagged model with motivation and social functioning reciprocally linked. We therefore

concluded that social functioning at 6 months was more likely to influence 12-month motivation than motivation at 6 months was to influence 12-month social functioning (figure 2).

Sensitivity Analysis

To evaluate the stability of these associations over a longer period of time, we tested the above models after aggregating outcome variables across the 12- and 18-month assessments. As opposed to conducting an independent evaluation of the 18-month time point, we aggregated these waves because missing data limited our power to test that model. These tests revealed that the primary relationships held through the 18-month time point: coefficients were comparable in effect size, and model fit indices were good and similar to the more constrained models. Findings from these analyses are presented in supplementary tables 4 and 5.

Discussion

In a large sample of patients with a first episode of psychosis drawn from 34 clinics across 21 states, motivation was associated with later occupational functioning, but occupational functioning was not associated with later motivation. The opposite association was found for the social domain: social functioning was associated with later motivation, but motivation was not associated with later social functioning. The associations were examined in participants after 6 months of treatment, controlling for baseline levels of these variables, and therefore likely reflect stable relationships that are less influenced by the immediate aftermath of a first episode of psychosis. Furthermore, the relationships were replicated in sensitivity analyses aggregating the 12- and 18-month time points, supporting the reliability of the main findings. The findings were also robust to important covariates, including demographic variables such as age, gender, and ethnicity, as well as treatment assignment.

Consistent with previous studies, findings suggest that motivation, as reflected by activation, drive, and goal

Fig. 1. Cross-lagged associations between motivation (Quality of Life Scale motivation, sense of purpose, and curiosity) and occupational functioning/work or school (Services Utilization Recording Form). *** $P < .001$, ** $P < .01$, * $P < .05$. Covariates include depression (CDSS) and psychotic symptoms (PANSS positive) at each time point, and cognition (BACS)—baseline and 12-month average. Unidirectional arrows indicate standardized regression coefficients; bidirectional arrows indicate covariances. Residuals of the autoregressive associations were allowed to covary.

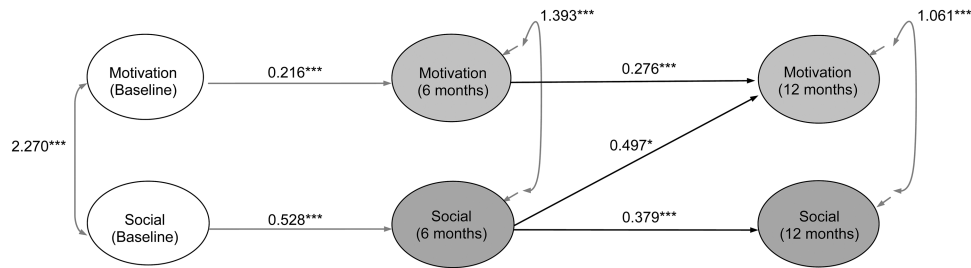

Fig. 2. Cross-lagged associations between motivation (Quality of Life Scale [QLS] motivation, sense of purpose, and curiosity) and social functioning (QLS interpersonal relations). *** $P < .001$, ** $P < .01$, * $P < .05$. Covariates include depression (CDSS) and psychotic symptoms (PANSS positive) at each time point, and cognition (BACS)—baseline and 12-month average. engagement, is especially critical to occupational functioning in young individuals who have recently developed a psychotic illness.⁴⁴ Such motivation in the occupational domain may be reflected by individuals identifying work or school goals, independently completing job or school re-enrollment applications, or actively seeking vocational and educational services. That levels of motivation were associated with work and school functioning, but not social functioning, was unexpected. While other factors such as cognition, interpersonal skills, and symptoms may also play a role in success at work or school, their importance may be secondary to the motivation to pursue engagement in those roles. Consistent with this idea, reported desire for work and active efforts to find work are strong predictors of competitive employment up to 2 years later in people with SZ.⁴⁵

Motivation was not associated with later social functioning; however, other variables not measured in this study may be more predictive of success in this domain, such as social skills/capacity, social support, and social cognition.^{16,46,47} While several studies have suggested that negative symptoms, including motivation, are associated cross-sectionally with social functioning, there is less evidence that motivation predicts social functioning over time.^{44,46,48,49} Social functioning may be more dependent on the acquisition of specific skills than is participation in work or school. Therefore, in the relative absence of concerted opportunities to learn social skills, motivation may be more strongly related to work or school participation. In addition, social skills training improves both negative symptoms and social functioning in SZ,⁵⁰ but has less impact on occupational functioning.^{51–53} As such, targeting receptive and expressive social skills may be more fruitful than targeting motivation for patients who report a desire to improve social relationships.

So why was social functioning associated with later motivation? Higher levels of social engagement and closer relationships may play a protective role in maintaining motivation in SZ, especially early on in the illness. Regular involvement in the lives of others and reciprocal relationships may provide important social validation and

acceptance that facilitates the rebuilding of confidence, self-esteem, and sense of purpose after the devastating effects of a psychotic episode.⁵⁴ Close and rewarding relationships may, in turn, support the articulation and pursuit of personal goals. Indeed, ample evidence suggests that the presence of relationships and degree of social support have lasting positive effects on the course of SZ.^{55,56} We are aware of one other prospective study examining reciprocal associations between motivation and psychosocial functioning in patients with SZ.²⁷ Nakagami et al reported that across a 1-year period in patients receiving community-based rehabilitative services, baseline psychosocial functioning predicted changes in motivation, while baseline motivation did not predict changes in functioning. We note, however, that in this study the sample was multi-episode SZ, and social and occupational functioning were combined into one outcome, precluding interpretation of differential outcomes.

While the QLS motivation items are strongly tied to other measures of amotivation/avolition,^{29,30} and have shown robust associations with psychosocial functioning in several studies,^{25,27} it is important to note that there are newer rating scales available that provide more comprehensive coverage of the multifaceted nature of experiential negative symptoms in SZ, including the assessment of motivation and pleasure across social, occupational, and recreational domains. The inclusion of scales such as the Clinical Assessment Interview for Negative Symptoms (CAINS¹⁹) or Brief Negative Symptom Scale (BNSS²⁰), for example, could improve our understanding of which qualities of experiential negative symptoms might be most critical for understanding psychosocial functioning over time. In addition, the inclusion of behavioral measures translated from animal models, such as those assessing effort-based decision-making (eg, Effort Expenditure for Rewards Task; EEfRT^{57,58}), could improve prediction of important psychosocial functioning outcomes in SZ. Finally, future studies should model relative *changes* in motivation and psychosocial functioning (eg, using latent growth curve modeling) to improve understanding of the associations of these constructs within people over time.

Our findings suggest that coordinated specialty care programs should target enhancement of motivation to support occupational functioning beyond the effects of evidence-based approaches such as supported education and employment. Conversely, if the goal is to maintain patient motivation, targeting social connection may be fruitful, such as in family-focused interventions. Ultimately, enhancing social relationships in the early phases of recovery may lead to distal improvements in occupational functioning through their impact on patient motivation.

Supplementary Material

Supplementary data are available at *Schizophrenia Bulletin* online.

Acknowledgments

Dr Fulford had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. *Conflict of Interest:* No sponsor or funder was involved in the design and conduct of the study; collection, management, analysis, and interpretation of the data; or preparation, review, or approval of the manuscript.
